⁴ — Abstract

While machine learning theory and theoretical computer science are both based on a solid mathematical foundation, the two research communities have a smaller overlap than what the proximity of the fields warrant. In this invited abstract, I will argue that traditional theoretical computer scientists have much to offer the learning theory community and vice versa. I will make this argument by telling a personal story of how I broadened my research focus to encompass learning theory, and how my TCS background has been extremely useful in doing so. It is my hope that this personal account may inspire more TCS researchers to tackle the many elegant and important theoretical questions that learning theory has to offer.

18 1 A Personal Story

My goal with this invited abstract, is to inspire more theoretical computer science (TCS) 19 researchers to engage in topics in machine learning theory. Being a TCS researcher myself, I 20 hope that by telling my own personal story - of how I adopted the field of learning theory -21 may provide a unique and more compelling argument than if a core learning theorist was 22 to attempt to convince you. Being a personal story, I will focus on some of the research 23 results I obtained along the way, and not so much on the broader learning theory and TCS 24 literature. The results I present have been chosen because they tell an interesting story and 25 showcase how core TCS concepts have proven useful in learning theory. Along the way, I will 26 tell some anecdotes on how these research projects started, and I will try to give you an idea 27 of some of the thought processes I initially went through when trying to enter a new field. 28 I have also tried to sprinkle in some advice for more junior researchers based on my own 29 experiences. Finally, I will also formally define some of the learning theory questions I have 30 studied, giving you an idea of what such questions may look like. I sincerely hope that you 31 find this somewhat unusual abstract refreshing. 32

³³ 1.1 My TCS Background and Connections Between Fields

For those who do not know me, let me start by briefly giving you my background, while also trying to convince you that many fields of TCS are deeply connected, and that it pays off to have a broad interest in TCS.

I started my Ph.D. studies in 2008 under the supervision of Professor Lars Arge at Aarhus University, Denmark. My initial research was on data structures, in particular so-called I/O-efficient data structures [2, 5], that take the memory hierarchy of modern hardware into account. Ever since I started my studies, I have always been curious and eager to learn new areas by interacting with great colleagues in the TCS community. This openness to collaborations and sharing of ideas is one of the strongest and most rewarding traits of our community.

3:2 From TCS to Learning Theory

Initially, my interactions with other researchers were through fellow students at the 44 department. I explicitly remember Allan Grønlund coming to my office with one of Mihai 45 Pătrașcu's beautiful papers [33] on data structure lower bounds in the cell probe model [35], 46 excitedly proclaiming that "this is so cool, we need to do this too!". At the time, I had never 47 had a complexity course or seen a real lower bound proof, and I was immediately hooked. 48 This led me on a long research journey trying to understand and develop the techniques for 49 proving lower bounds on the efficiency (space, query time, update time) of data structures, 50 see e.g. [23, 24, 29] for some highlights. 51

While cell probe lower bounds were my main focus for years, I always found research that 52 bridges several fields the most exciting. The earliest such example in my own research started 53 with a visit by Jeff M. Phillips in our research group. During his visit, Jeff introduced me to 54 discrepancy theory while explaining some of his recent work. As discrepancy theory will be 55 important later, let me give a rough definition of it here. At its core, discrepancy theory 56 studies the following problem: Given a matrix $A \in \mathbb{R}^{m \times n}$, compute a coloring $x \in \{-1, 1\}^n$ 57 minimizing the discrepancy $||Ax||_{\infty}$. Understanding the best achievable discrepancy for 58 various types of matrices is an old and very well-studied topic in TCS [3, 34, 10, 7, 31]. In 59 particular, I recall Jeff telling me about a result of Banaszczyk [6] showing that matrices with 60 sparse columns always have low discrepancy colorings. While being intellectually intrigued 61 by this result, I did not see any immediate applications of it in my own research. However, a 62 couple of months later, Elad Verbin, a post doc in our group at the time, suggested to me 63 that I should try to prove data structure lower bounds in the *group model*. Without going 64 into details here, it turns out that Banaszczyk's discrepancy result could be used to directly 65 translate decades of research on discrepancy lower bounds into group model data structure 66 lower bounds [25]. The connection even improved some of the discrepancy upper bounds 67 using data structure upper bounds as well. 68

This theme of connecting areas has proven very useful over the years. It for instance 69 got me started on *streaming algorithms* when Jelani Nelson and Huy L. Nguyen asked 70 whether we could use cell probe lower bound techniques to prove *time* lower bounds for 71 streaming algorithms [27]. In later work with Jelani [26], we similarly proved optimality of the 72 Johnson-Lindenstrauss (JL) lemma [21] in dimensionality reduction using an encoding-based 73 argument. Such arguments were typically used in cell probe data structure lower bounds. As 74 it will be important later, let us recall that the JL lemma says that any set of n points in 75 \mathbb{R}^d can be embedded into $O(\varepsilon^{-2} \log n)$ dimensions while preserving all pairwise distances to 76 77 within a factor $1 \pm \varepsilon$.

Another interesting example was initiated during a visit at MIT in 2017 where Vinod 78 Vaikuntanathan was telling me how "data structures and crypto are a match made in heaven". 79 This claim got me curious, and after returning home, I read a bit on data structure in 80 cryptography and stumbled on Oblivious RAMs (ORAMs) [17]. An ORAM is basically a 81 primitive for obfuscating the memory access pattern of an algorithm, such that the memory 82 accesses reveal nothing about the data stored. Checking the references of the papers I was 83 reading, it turned out that a crypto Professor sitting just down stairs, Jesper Buus Nielsen, 84 had made multiple contributions to ORAMs. After some brief initial discussions, we quickly 85 realized that cell probe lower bound techniques could be tweaked to prove strong lower 86 bounds for ORAMs [28]. This connection started a whole line of research into lower bounds 87 for ORAMs and related primitives in crypto. 88

Finally, let me mention one last example outside learning theory. Back in 2017, I was attending a communication complexity workshop in Banff, where Mark Braverman was giving a talk about some work of his [11] on a conjecture in information theory/network coding [30].

The conjecture relates to communication networks, where a network is modeled by a graph 92 with capacities on the edges, designating how many bits may be sent across. The conjecture 93 then says that for undirected graphs (messages may be sent in both directions), if we are 94 given k source-sink pairs that each need to send an r bit message from source to sink, then 95 the largest number of bits r we can handle without violating capacity constraints, is equal to 96 the multi-commodity flow rate. Intuitively, this means that the best you can do is to simply 97 forward your messages as indivisible bits. Mark's talk was excellent, but at the time, I had 98 no immediate applications of his result. However, while spending a semester at the Simons 99 Institute in 2018, a coincidental conversation with MohammadTaghi Hajiaghayi led us [15] 100 to proving conditional lower bounds for I/O-efficient algorithms using the information theory 101 conjecture that Mark presented. Needless to say, it was quite satisfactory to come full circle 102 and address the topic that started my Ph.D. studies. In addition to the lower bounds for 103 I/O-efficient algorithms, the conjecture also gave a clean conditional $\Omega(n \log n)$ lower bound 104 for constant degree boolean circuits for multiplication [1]. I find it quite fascinating how two 105 such seemingly different problems of multiplication and communication in graphs may prove 106 to be so intimately connected. 107

If there is one message to take away from my own experiences, in particular for junior researchers, it must be that many things are deeply connected and you never know when results in one branch of TCS may prove useful in another. That is one of its beauties. I would thus strongly recommend that you attend talks, seminars, and generally engage in discussions with the many brilliant TCS researchers, also in fields outside your own immediate interest. Build your expertise in one area, but always be curious and look for connections and inspiration from others.

115 **1.2 Entering Learning Theory**

Now let me get to the promised topic of entering learning theory from a TCS background, 116 and how this background proved extremely useful. For me, this journey started around 117 2019. As you all know, machine learning was the big hype at the time, and probably still 118 is. Like many others, I initially found deep neural networks and what they could do quite 119 fascinating. This led me to consider whether I should get into machine learning and work on 120 this extremely hot topic. However, after getting a slightly better understanding of the field, I 121 quickly found that training a deep neural net and running some experiments on a benchmark 122 data set, to be much more engineering and craftsmanship than deep stimulating thoughts. 123 And with all the obligations that come with a faculty position, I just did not have the time 124 to learn the practical skills that it takes to make efficient and competitive implementations. 125 And probably was not that interested in it after all. I almost abandoned machine learning, 126 had it not been for a student of mine, Alexander Mathiasen. Alexander was very independent 127 and eager to get into machine learning. He had realized that I was more interested in theory 128 questions and had on his own discovered the great source of open problems in learning theory 129 that are published with the COLT proceedings. The open problem Alexander had found 130 was related to a technique called *boosting*. Let me start by introducing the general idea in 131 boosting and the setup for binary classification in supervised learning. 132

¹³³ Supervised Learning and Boosting

In supervised learning, a binary classification problem is specified by an input domain \mathcal{X} , an unknown target function $f : \mathcal{X} \to \{-1, 1\}$ and an unknown data distribution \mathcal{D} over \mathcal{X} . A learning algorithm receives as input a training data set of n i.i.d. samples $(x_i, f(x_i))$ with

3:4 From TCS to Learning Theory

each $x_i \sim \mathcal{D}$. The goal of the learning algorithm is to output a classifier $h: \mathcal{X} \to \{-1, 1\}$ minimizing the probability of misprediction the label of a new sample from \mathcal{D} , i.e. where er $_{\mathcal{D}}(h) := \Pr_{x \sim \mathcal{D}}[h(x) \neq f(x)]$ is as small as possible. To have an example in mind, think of \mathcal{X} as the set of all images of a particular size and f as the hard-to-specify function that maps every image of a mammal to -1 and every other image to 1. The learning problem is thus to train a classifier that can detect whether an image contains a mammal or not.

Boosting is then a powerful and elegant idea that allows one to combine multiple inaccurate 143 classifiers into a highly accurate *voting classifier*. Boosting algorithms such as AdaBoost [16] 144 work by iteratively running a base learning algorithm on reweighed versions of the training 145 data to produce a sequence of classifiers h_1, \ldots, h_t . After obtaining h_i , the weighting of the 146 training data is updated to put larger weights on samples misclassified by h_i , and smaller 147 weights on samples classified correctly. This effectively forces the next training iteration to 148 focus on points with which the previous classifiers struggle. After sufficiently many rounds, 149 the classifiers h_1, \ldots, h_t are finally combined by taking a (weighted) majority vote among 150 their predictions. This idea also goes under the name of *multiplicative weight updates* and 151 has many applications in TCS. 152

Boosting works exceptionally well in practice and much theoretical work has gone into 153 explaining its huge success. One important line of work in this direction is based on the 154 notion of margins [8]. A voting classifier g may be written as $g(x) = \operatorname{sign}(\sum_{i=1}^{t} \alpha_i h(x))$ with 155 $\alpha_i \in \mathbb{R}$. If we normalize the weights so that $\sum_i |\alpha_i| = 1$, then $\sum_{i=1}^t \alpha_i h_i(x) \in [-1, 1]$. The 156 margin of g on a sample $(x, y) \in \mathcal{X} \times \{-1, 1\}$ is then defined as $y \sum_{i=1}^{t} \alpha_i h_i(x)$. The margin 157 is thus a number in [-1, 1] and can be thought of as a confidence in the prediction. If the 158 margin is 1, then all classifiers combined by g agree and are correct. If the margin is 0, then 159 we have a (weighted) 50-50 split between the two possible predictions -1/1, and so on. It 160 has then been proved that voting classifiers g with large margins on all training samples 161 (x_i, y_i) have a small $\operatorname{er}_{\mathcal{D}}(g)$ [8]. 162

¹⁶³ Boosting and Discrepancy Theory

Now let me return to the open problem Alexander approached me with. Since voting classifiers 164 with large margins have a small $e_{\mathcal{D}}(g)$, it seems natural to develop boosting algorithms that 165 obtain large margins by combining few base classifiers, i.e. with a small t. This leads to faster 166 predictions and possibly also faster training. The question now is as follows: If the best 167 possible margin on all training samples is γ^* when one is allowed to combine arbitrarily many 168 base classifiers h_i , then how large margins can we obtain by combining t base classifiers? 169 The best known algorithm obtained margins of $\gamma^{\star} - O(\sqrt{\log(n)/t})$ with n training samples, 170 and the best known lower bound showed that this is tight whenever $t \leq n^{1/2}$. The conjecture 171 stated that this remains tight for $t \leq n \log n$. 172

In my first learning theory paper [32], we observed an interesting connection between 173 this question and discrepancy theory. In more detail, we considered the matrix A obtained 174 by forming a row for each training sample (x_i, y_i) and a column for each h_i in a voting 175 classifier $g(x) = \text{sign}(\sum_{j=1}^{t} \alpha_j h_j(x))$. The entry corresponding to (x_i, y_i) and h_j stores the 176 value $y_i \alpha_j h_j(x)$. Notice that the sum of the entries in the *i*'th row is precisely the margin of 177 g on (x_i, y_i) . Next, if we can find a coloring $x \in \{-1, 1\}^t$ such that $||Ax||_{\infty} \approx 0$, then this 178 means that for every single row of A, the sum over the columns j where $x_i = 1$ is almost 179 exactly the same as the sum over columns where $x_i = -1$. Thus if we replace g by a new 180 voting classifier where we set all α_j to 0 when x_j equals the majority of -1/1's in x, and to 181 2 when x_i is the minority, then the new g' has almost exactly the same margins as before 182 but uses only half as many base classifiers. Recursively finding a low discrepancy coloring 183

K. G. Larsen

x using the celebrated Spencer's six standard deviations suffice result [34], we were able to refute the conjecture on the tradeoff between t and the achievable margin while establishing yet an interesting connection between discrepancy theory and other areas.

¹⁸⁷ Support Vector Machines, Sketching and Teaching

Around the same time as our first learning theory results, I had voluntarily started teaching 188 the Machine Learning undergraduate course at Aarhus University. Never having followed 189 such a course myself, this was a great way of forcing myself to learn the basics. But beyond 190 learning the basics, teaching also led to new research questions. After having completed 191 the first project on boosting, we naturally started reading up on the references proving that 192 large margins lead to small $\operatorname{er}_{\mathcal{D}}(g)$. Such results are referred to as generalization bounds 193 and are a cornerstone of learning theory. Studying the classic proofs of generalization for 194 large margin voting classifiers [8], there seemed to be an underlying idea of *sketching* or 195 compressing the voting classifier g while exploiting that it has large margins. Intuitively, if 196 there is a small-bit representation of g, then there are only few choices for g. A union bound 197 over all these choices shows that it is unlikely that there is even a single g that performs 198 great on the training data (has large margins) and poor on new data (has large $er_{\mathcal{D}}(q)$). 199

Around the same time, I had just taught Support Vector Machines (SVMs) [14]. SVMs 200 are another type of learning algorithm where the input domain \mathcal{X} is \mathbb{R}^d . In the simplest 201 setup, when given a training set of n samples $(x_i, y_i) \in \mathbb{R}^d \times \{-1, 1\}$ with $||x_i|| \leq 1$ for all 202 i, SVM searches for the separating hyperplane with the largest margin to the data. In the 203 context of SVMs, if we assume for simplicity that a hyperplane passes through the origin and 204 has unit length normal vector $w \in \mathbb{R}^d$, then we predict the label of a new point $x \in \mathbb{R}^d$ by 205 returning sign $(w^T x)$. The margin of the hyperplane on a labeled point (x, y) is then defined 206 as yx^Tw . The margin is positive if the hyperplane correctly predicts the label of (x, y) and 207 the absolute value of the margin measures how far the point is from the hyperplane itself. 208

Similarly to the case for boosting, there were known generalization bounds [9] stating 209 that if a hyperplane h has large margins, then $er_{\mathcal{D}}(h)$ is small. However, these bounds were 210 proved in a completely different way than the boosting bounds and seemed to be sub-optimal. 211 In our work [18], we improved these generalization bounds by observing a connection to 212 the Johnson-Lindenstrauss (JL) lemma [21] that I previously worked on [26]. Shortly after 213 the lower bound for JL by Jelani and I, Noga Alon and Bo'az Klartag [4] presented an 214 alternative proof that at its core gives a randomized sketch for representing a set of n unit 215 length vectors in \mathbb{R}^d using $O(\varepsilon^{-2} \log n)$ bits for each vector, while preserving their pairwise 216 inner products up to additive ε . Our idea was then to apply this sketch to w and the training 217 data. Since $w^T x$ changes by only additive ε , the sketched hyperplane \tilde{w} remains correct (i.e. 218 $\operatorname{sign}(\tilde{w}^T x) = \operatorname{sign}(w^T x) = y$ if the margin was larger than ε before sketching. In this way, 219 we get a compression whose size depends on the margin. Combining this with the union 220 bound idea mentioned earlier led to improved generalization bounds for SVMs. 221

222 Replicable Learning and Sketching

Let me give another example where the JL lemma proved useful in learning theory. In a very exciting line of work, starting with [20], core TCS researchers introduced the notion of *replicable learning* as an attempt at addressing issues with reproducibility of results in machine learning. Here the basic setup is that you want to develop learning algorithms \mathcal{A} , such that if \mathcal{A} is run on two sets S and S' of n i.i.d. samples from the same distribution \mathcal{D} , then we should get the same output with high probability. The intuition is thus, if you rerun

3:6 From TCS to Learning Theory

²²⁹ someones replicable algorithm on your own data set, you will get the same results as they ²³⁰ did on their data set, provided that the data set is sampled from the same distribution. To ²³¹ help you in this seemingly difficult task, the two executions of \mathcal{A} share a random seed. This ²³² may be justified in practice by publishing the seed of a pseudorandom generator along with ²³³ your machine learning paper and experimental results. There is naturally a ton of problems ²³⁴ to revisit in replicable learning and some strong connections with *differential privacy* have ²³⁵ already been established [12].

In a recent result [22], we considered SVMs in the replicable setting. Here we are 236 promised that there exists a hyperplane with all margins at least γ on the support of the 237 data distribution \mathcal{D} , and must replicably compute a hyperplane h with small $e_{\mathcal{D}}(h)$. The 238 key idea in our work is quite simple: partition the training data into t chunks and run SVM 239 on each to obtain hyperplanes with normal vectors w_1, \ldots, w_t . Average these normal vectors 240 $w = t^{-1} \sum_i w_i$ and apply the sketching technique by Alon and Klartag [4] to w. The first 241 main observation is that computing the average w reduces variance compared to each w_i . 242 Thus for two independent but identically distributed training data sets S and S', the resulting 243 w and w' will be close. The key property of the sketching technique of Alon and Klartag is 244 that such close vectors are very likely to be "rounded" to the same hyperplane/sketch if we 245 share a carefully chosen random seed. 246

247 Multi-Distribution Learning, Discrepancy Theory and NP-Hardness

Let me conclude with one last example of TCS techniques playing a key role in learning 248 theory results. A recent line of work in learning theory has studied learning in a setup with 249 multiple data distributions. Formally, we have k distributions $\mathcal{D}_1, \ldots, \mathcal{D}_k$ over $\mathcal{X} \times \{-1, 1\}$ 250 and the goal is to train a classifier that performs well on all k distributions simultaneously. 251 For this purpose, we are given a hypothesis set \mathcal{H} containing hypotheses $h: \mathcal{X} \to \{-1, 1\}$. 252 As an example, think of \mathcal{H} as all hyperplanes in \mathbb{R}^d . If we let $\tau = \min_{h \in \mathcal{H}} \max_i \operatorname{er}_{\mathcal{D}_i}(h)$ 253 denote the best achievable max-error of any $h \in \mathcal{H}$, then the goal is produce a classifier 254 $f: \mathcal{X} \to \{-1, 1\}$ with $\max_i \operatorname{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$ using as few training samples as possible. 255

It is known that for a single distribution \mathcal{D} , this task requires $\Theta(d/\varepsilon^2)$ samples and it is 256 straight forward to generalize the algorithm to $O(dk/\varepsilon^2)$ samples for k distributions. Very 257 surprisingly, it turns out that this can be improved to essentially $O((d+k)/\varepsilon^2)$ samples using 258 boosting ideas [19]. However, the upper bounds achieving this number of samples are cheating 259 a little. Concretely, they do not output a single hypothesis f with $\max_i \operatorname{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$. 260 Instead, they output a distribution \mathcal{D}_f over hypotheses such that $\max_i \mathbb{E}_{f \sim \mathcal{D}_f}[\operatorname{er}_{\mathcal{D}_i}(f)] \leq \tau + \varepsilon$. 261 Attempting to *derandomize* this does not seem to work as we only have Markov's inequality 262 to argue that with constant probability, a random $f \sim \mathcal{D}_f$ has $\max_i \operatorname{er}_{\mathcal{D}_i}(f) = O(k(\tau + \varepsilon))$. 263 In a current manuscript, we show that there is a good reason why this is the case. Concretely, we prove via a reduction from discrepancy minimization that it is NP-hard to compute an 265 $f: \mathcal{X} \to \{-1, 1\}$ with $\max_i \operatorname{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$. Here we use a result of Charikar et al. [13] 266 stating that it is NP-hard to distinguish whether, for a given a 0/1 matrix A, there exists 267 an $x \in \{-1,1\}^n$ with Ax = 0, or whether all $x \in \{-1,1\}^n$ have $||Ax||_{\infty} = \Omega(\sqrt{n})$. In our 268 reduction, we think of the columns as the input domain \mathcal{X} and we form a distribution for each 269 row of A. The key idea is to show that if a learning algorithm computes an $f: \mathcal{X} \to \{-1, 1\}$ 270 with $\max_i \operatorname{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$, then the predictions made by f on the columns must give a low 271 discrepancy coloring that can distinguish the two cases. 272

While showing NP-hardness is by now completely standard in TCS, let me add that my two coauthors are both from Statistics. They had heard NP-hardness mentioned before, but never used it, and found quite some joy in getting to apply it on a relevant problem. I guess the experience shows that what may be common tools in one discipline may be highly novel in another.

278 1.3 Conclusion and Thoughts

To summarize my research journey into learning theory, I hope that I convinced you that 279 many techniques and tricks from TCS are extremely useful. Not only do they help in 280 addressing learning theory questions, but they also bring an interesting new direction to the 281 field, such as e.g. arguing computational hardness of training a classifier. Furthermore, this 282 transfer of techniques is not isolated to learning theory, but has been a guiding principle in 283 all my research since the early days of my Ph.D. studies. Keep your eyes open for surprising 284 connections between seemingly disjoint topics - they are often hiding just below the surface. 285 To me, the questions studied in learning theory are as clean, elegant, beautiful and 286

well-defined as any TCS topic, and are very well fit for anyone with a TCS background. 287 What has worked well for me, has been to start in some corner (coincidentally boosting 288 for me) and get to know the literature and related questions. Then as you have a better 289 understanding and overview, you can start approaching neighboring questions and growing 290 your focus. I suppose this is not much different from starting your Ph.D. studies by working 291 on a narrow topic and broadening out as you mature. Finally, do not underestimate the 292 value of talking to peers and attending talks for inspiration. As a newcomer, it is sometimes 293 hard to ask the right question, and calibrating with an expert is very useful. Also, the COLT 294 open problems have been a good source of inspiration as you at least know that some experts 295 in the field find the question interesting. 296

I strongly hope that this abstract may inspire some of you to work on learning theory, or give you the courage to enter a new field that you find intriguing, knowing that your TCS skills are useful in many surprising places.
